Socio-economic deprivation and health outcomes in Ialomiţa County (Romania)

Ana-Maria Taloş

University of Bucharest, Romania

Several health researchers have emphasised the effects of socio-economic factors on population health outcomes. Many studies have been demonstrating the relationship between socio-economic conditions and individual health, as they have stated that deprived population are more likely to have a higher rate of morbidity and mortality due to different diseases. This study examines the association between socioeconomic deprivation and health outcomes among the population from urban and rural communities in Ialomiţa County (Romania). The research is based on statistical and spatial analysis, using indicators related to socio-economic deprivation (economic status index, housing endowment index, education level index and) and indicators related to health outcomes. Preliminary results showed the expansion of deprived areas, overlapping areas with precarious population health, generally areas with high incidence of respiratory and digestive diseases, high mortality due to infectious diseases.

Key Words: socio-economic deprivation, composite indices, health inequalities, population health, health outcomes.

Article Info: Received: March 2, 2017; Revised: October 1, 2017; Accepted: November 3, 2017; Online: November 25, 2017.

Introduction

Health is an important dimension of society, health issues being frequently associated with determinants as the physical and social environment, population health behaviour, healthcare access and quality care. Usually, the social determinants of health are considered the key-problem in shaping territorial differences, as the social environment could be associated with several aspects which
satisfy and fulfill other basic human needs (Mahadevana & Hoang, 2016). Vietnam, as earnings can be spent on a wide range of goods and services to considered a significant determinant of multidimensional deprivation in use and higher health care costs (Zhao et al., 2011). In the same way, income is associated with fewer number of diseases, many illnesses being registered outcomes in various places, based on quantitative or qualitative indicators. Sociology has been defined by Townsend (1987) as a state of observable and demonstrable disadvantages relative to the local community to which an individual belongs. According to Townsend, these disadvantages could have the social or material origin as social fragmentation, poverty, illiteracy, deprivation being closely linked to well-being and health. Townsend proposed for the first time an index to evaluate the socio-economic deprivation among the population, by considering different socioeconomic variables: unemployment rate, housing density, individuals without a car and a house in property. After Townsend research, a wide range of studies have proposed, using different methods and techniques to construct deprivation indices: Bell, Schuurman & Hayes (2007); Cabrera Barona et al. (2015); Lalloue et al. (2013); Pasetto, Sampaolo and Pirastu (2010), Zamfir, Dumitrache et al (2015) etc.

In order to estimate the relative deprivation of an area, some demographic, social and economic characteristics have also been considered in different studies. According to the approach, the availability and data reliability, complex indices have been constructed by taking into account various indicators related to economic status, education level or living conditions. Haase and Pratschke (2012) considered the major socioeconomic inequalities as education level, unemployment, professional classes, and lone rates, while for Schuurman et al. (2007), income, education, employment and family structure prevail.

In many of these studies, some common elements could be found: education, income, employment, living conditions, representing essential components associated with social and economic determinants of population health. Socioeconomic deprivation could be associated with areas characterised by social exclusion limited access to clean water, household overcrowding, unemployment, lack of formal education etc. (Havard et al., 2008) and precarious population health outcomes (Boyle, Gatrell & Duke-Williams, 2001).

Using also multi-criteria or participatory approaches, different studies tried to demonstrate the relationship between socioeconomic conditions and health outcomes in various places, based on quantitative or qualitative indicators. According to Marmot & Bell (2012), proper living conditions and decent income are associated with a fewer number of diseases, many illnesses being registered among the poor than the wealthy population. According to other studies, socioeconomic deprivation has been correlated with increasing rate of hospital-use and higher health care costs (Zhao et al., 2011). In the same way, income is considered a significant determinant of multidimensional deprivation in Vietnam, as earnings can be spent on a wide range of goods and services to satisfy and fulfill other basic human needs (Mahadevana & Hoang, 2016).
A number of studies have assessed the direct relationship between illness and inadequate urban housing conditions, poor infrastructure or overcrowding being associated with precarious health (Galea & Vlahov 2005). Also, people living in wealthy neighbourhoods have a lower risk of contracting diseases compared to people living in poor ones (Pampalon & Raymond, 2000). A good correlation between long-term illness and deprivation has also been demonstrated in England and Wales (Haynes & Gale, 1999). Various methods were established to calculate composite indices, and there are several alternatives in producing aggregated indicators. However, the reliability and validity of data used are the most important as the different type of data could be combined (OCDE, 2008).

‘Social deprived’ areas are defined by a combination of census measures that include high unemployment, low-status occupation, overcrowded living conditions, low share of homeowners and cars, and high proportions of vulnerable people living alone (Watt & Sheldon, 1993).

Starting from these studies, this paper attempts an estimation of relative deprivation in a plain area, Ialomiţa County, close to the capital city (Bucharest), by using a complex index according to the availability of data.

The present research aims to analyse the relationship between population health outcomes and socio-economic deprivation, by using a number of indicators related to economic status, education level and housing conditions. These indicators were correlated with different health outcomes. The precarious health status of the population, the economic decline registered in the last period (being one of the poorest counties in Romania), as well as the expansion of unemployment and social instability (Talos, 2017), were reasons in selection Ialomiţa County as the study area. An important limitation of the study is the lack of various categories of data at the micro territorial level, the reduced availability and reliability of data, influencing the selection of indicators which were considered in constructing the composites indices.

Methodology

In order to analyse the relationship between socio-economic deprivation and population health outcomes in Ialomiţa County, statistical and spatial analysis have been used. To evaluate the socio-economic deprivation, three important components were considered: economic status, education level and housing endowment, based on various indicators. Using available data from the 2011 Census of Population of Romania, a complex index of socio-economic deprivation has been calculated. The complex index of socio-economic deprivation resulted from the standardization and aggregation of the three composite indices: economic status index, education level index and housing endowment index (Zamfir, Dumitrache et al., 2015) (Table 1).

The economic status index was based on (1) percentage of the unemployed population, (2) percentage of the inactive population, (3) percentage of the economically dependent population and (4) percentage of the retired population. The indicators considered for the analysis of the housing endowment index are important in determining the comfort degree and the quality of life of the
inhabitants: (1) the ratio of persons per room (overcrowding), (2) percentage of households without access to drinking water from the public system, (3) percentage of households without bathrooms, (4) the ratio of persons per household.

The education level index took into account a set of four socio-economic indicators: (1) percentage of the population without any level of formal education or instruction, (2) percentage of the illiterate population, (3) percentage of women with secondary education and (4) percentage of women with higher education.

The values of the socio-economic deprivation index were between 0 and 1, the higher values being associated with higher deprivation.

Bivariate correlation has been performed (Pearson correlation) between composite indices of socio-economic deprivation index, in order to specify the strength and direction of the relationship between variables.

Correlations between socio-economic deprivation index and each of the three composite indices has been conducted (economic status index, housing endowment index, education level index). As the significance level must be less than 0.001, statistically significant correlations are between education level index and housing endowment index \( (r=0.69, \text{df}= 64, p<0.001) \), housing endowment index and socio-economic deprivation index \( (r=0.82, \text{df}= 64, p<0.001) \), socio-economic deprivation index and education level index \( (r=0.85, \text{df}= 64, p<0.001) \), socio-economic deprivation index and economic status index \( (r=0.67, \text{df}= 64, p<0.001) \) (Table 2). There is a significant relationship between the three composite indices and socio-economic deprivation index, enabling that unemployment, living conditions and education could be considered as socio-economic variables for the present study.

Pearson correlation has also been used to show the relationship between socio-economic deprivation and health outcomes (morbidity due to digestive and respiratory diseases, mortality due to infectious diseases and tuberculosis). Data related to health outcomes have been provided by Ialomița Public Health Directorate and Ialomița Directorate of Statistics. The territorial inequalities related to deprivation and health outcomes have been evidenced by using an open source program Quantum GIS 2.8.4.

Results and discussion

The assessment of socio-economic deprivation outlines significant territorial inequalities, as the values of the socio-economic deprivation index ($Id$) varying from 0.144 to 0.895, emphasising several deprived areas. In the present study, a deprived area is associated with high rate of unemployment and illiteracy, limited access to basic services and facilities (safe drinking water, sewerage, flush toilets). The variations of $Id$ values resulted from the different influence of composite indices.

**Economic status**

Values of economic status index highlight territorial inequalities particularly as a consequence of high unemployment in many rural localities, unemployment rate exceeding 10 or 15% and more than 12% of the active population are unemployed (Figure 1).

It has been already suggested that unemployment is more reliable and updatable indicator of social deprivation than the composite indices for small areas generally (Haynes et al., 1996). Unemployment indicates an inconsistency on the labour market, and the highest values are registered in poor and under-developed areas. The high share of inactive people leads to imbalance the local economy, as there are not enough active people to provide income, retirement fee, allowances etc.

In the same way, there is a statistical relationship between health outcomes and unemployment, due to different processes: on one hand, people with illness have a higher unemployment probability than people with good health (Arrow, 1996) and, on the other hand, that health status deteriorating while being unemployed due to stress caused by this unhappy life event (Kessler et al., 1987). Economically deprived areas are located in the east part (between Fetești and Tândărei) and central part (around Căzănești city) of Ialomița County, overlapping areas with a high unemployment rate, a high share of retired
population and a significant percentage of the economically dependent population. The reduced number of working places indicate a vulnerable economic system that easily transposes into deprivation.

Population from rural areas are particularly facing great difficulties in finding employment due to the low level of education or qualification, but on the other hand, there are few investments in the rural area, and a reduced working places offer. For the unemployed people, health problems can come along with the stress and with the limited amount of money available in case of health issues (Figure 1). In a county with 53.9% of the population living the rural area and 16.5% representing seniors, the ageing population is an important element to consider in analysing socio-economic deprivation. In many localities from Ialomiţa County, over 40% of the population are economically dependent. This aspect could be associated with a higher rate of morbidity and mortality in affected areas (Figure 1).

**Housing endowment**

Housing endowment index also reveals territorial inequalities, deprived areas from this point of view being located in the west (rural localities near Urziceni city), central (rural localities around Căzăneşti city) and east part of the county (rural localities between Tândărei and Feteşti).

Poor housing conditions could be associated with personal problems, like adopting unhealthy behaviours, because of the stress brought by housing difficulties, affordability and overcrowding places (Pollack & Lynch, 2009). Moreover, crowded conditions are also linked with different health problems: respiratory infections, household accidents or infectious diseases (Bashir, 2002).

Variations of housing endowment index outline also difference in living conditions due to overcrowding, difficult access to safe drinking water and absence of facilities such as flush toilets and sewerage. Rural areas are the most disadvantaged as the higher values of the index are in rural localities, especially those from the east part of the county, and the local population is exposed to

Socio-economic deprivation and health 247

various diseases (Figure 2). Deprived areas overlap almost the whole county, excepting four cities (Slobozia, Urzici, Amara and Fetești), generally many of the dwellings have no water supply (76.25%) or inside bathrooms (79.65%), increasing the risk of infectious, respiratory or digestive system diseases (Figure 4).

Education level

Education level is another important determinant of socio-economic deprivation, as education was identified in several studies as an indicator of deprived areas and health outcomes: the higher the proportion of illiterate people, the increased risk of chronic or infectious diseases (Braveman et al., 2010). The higher the proportion of women with secondary and higher education, the higher the literacy potential of their children and the lower is the risk of precarious hygiene (Nagahawatte & Goldenberg, 2008). Education usually shows a relationship with self-rated health such that those with the highest education have the best health and those with lowest education have the worst health. But socioeconomic gradients, including education, must be contextualized within social circumstances (Pearson, 2008). Education became a gradient in the range of health status, disability or chronic conditions, as those with less education have slightly worse health and the best health outcomes are for those with the highest education. That is why, persons who have completed more years of education have better health compared to those who have fewer years of schooling (Braveman et al., 2010).

The territorial analysis highlights differences among Ialomita County population by education level and residence: high rate of illiterate population (3.97%), deficiency of population that has graduated a school (7.13%) and a low share of women with secondary and high education (37%), mainly in the rural areas (Figure 3). The maximum values of the indicators considered for the education index are recorded in Bărbulești, a village close to Urzici city: 33.18% is represented by population without graduated school, 27.6% are

Figure 2. Housing endowment (2011)
illiterate, there are no women with superior education and 7.37% of women have secondary education. Generally, the education level index is relatively high across the study area, with averages exceeding 0.250 (Figure 3).

Socio-economic deprivation

High unemployment rates, increased death rates and negative deprivation scores in rural areas outline the presence of disadvantaged people with poor health (Fearn, 1987). Deprivation is a phenomenon that mostly affects the remote areas from Ialomița County, where the unemployment rate is high (16.47%), the share of inactive population surpasses 51.79% and percentage of the illiterate population represents 3.97% (according to insse.ro, 2011). The most deprived areas are located in the central (around Căzănești city) and east part of the county (between Tândărei and Fetești), including a number of 52 localities and affecting around of 50,000 inhabitants.

The results reflect issues related to lack of basic infrastructure and services, deficiencies in providing drinkable water, lack of facilities (sewerage, bathrooms - 78% have no flush toilets), overcrowding, poor access to healthcare services.

While at the national level the socio-economic deprivation index records average value of 0.383 (Zamfir, Dumitrache et al., 2015), in Ialomița County the situation is worse, the average values surpassing 0.430. Cities as Slobozia, Urziceni, Fetești and Amara are less confronting with issues as low education level, poor housing conditions and unemployment as well as rural localities surrounding these cities where the population has to access to education, working places and facilities from the urban area (Figure 4).

Areas recording the highest values of socio-economic deprivation index are also registering higher values of all composite index. However, there are localities where housing endowment index exceeded average values, contributing significantly to the increase of socio-economic deprivation index (Id) value, namely to worsening of the situation. For example, many little towns as Fierbinți-Târg (in the eastern extremity of the county), which don’t have urban

---

**Figure 3. Education level (2011)**

- under 0.300
- 0.300 - 0.400
- over 0.400
characteristics or facilities, being included in the category of ‘towns’ during the communist period just for balancing the urban-rural gap. Communities like Bârbulești and Roșiori, located in the west part of the county, recorded higher values of education level index (\(Ie\)). This situation is based on cultural reasons that determine an increased rate of illiterate population and decreased the share of women without secondary or superior education.

There are also areas where the economic status index (\(Iec\)) has the largest contribution, as there is a considerable share of the population of working age that is unemployed and also a great part of them are socially assisted. This happens particularly in the east part of the county, in localities as Tândărei and Gheorghe Doja, where over 15% of the active population is unemployed as there are few working places available (Figure 4).

Health outcomes
Economic and social deprivation has an important contribution to mortality, as this contribution increases gradually with the level of deprivation. The variation in deprivation is closely linked to variation in premature mortality (Pampalon et al., 2009).

In Ialomița County, mortality due to digestive and respiratory system diseases, as well as infectious diseases is higher than other regions of the country. Higher rate of mortality due to these diseases are registered in both rural and urban areas, but the values of these indicators are significantly higher in deprived areas located in a central and eastern part of the county.

One of the major problem related to these deprived areas is represented by the largest extent of infectious diseases, particularly in the eastern part of the county in localities situated at a great distance to the nearest city (Figure 5).

Also, the morbidity due to respiratory and digestive system diseases is higher in these deprived areas, overlapping regions with poor economic status, improper living conditions and precarious education level. Generally, the deprived areas from the centre and east part of the county are overlapping

![Figure 4. Socio-economic deprivation (2011)](image-url)
areas with precarious population health outcomes (high incidence of respiratory and digestive diseases, and high level of mortality particularly due to infectious, respiratory or digestive diseases).

Pearson correlation between socio-economic deprivation index components and specific mortality and morbidity show significant associations. Only the significance level under 0.001 are considered, meaning that statistically significant correlations are between mortality due to infectious diseases and mortality due to tuberculosis ($r=0.85$, df = 64, $p<0.001$), morbidity due to respiratory diseases and economic status index ($r=0.32$, df = 64, $p<0.001$), morbidity due to respiratory diseases and housing endowment index ($r=0.41$, df = 64, $p<0.001$), morbidity due to digestive diseases and housing endowment index ($r=0.27$, df = 64, $p<0.001$).

There is no significant correlation between mortality due to infectious diseases and economic status index, too. There is a poor correlation between education level and mortality due to respiratory diseases. The reduced data availability could explain these inconsistency. Social and economic deprivation explained more of the variation in inequalities in health outcomes. Better level education, decent living conditions and higher economic status could improve population health outcomes (Figure 6).

**Conclusions**

The study aimed to analyse the relationship between population health outcomes and socioeconomic deprivation in Ialomiţa County, identifying territorial inequalities. Deprived areas overlap regions with high incidence of respiratory and digestive diseases and high level of mortality due to infectious, respiratory or digestive diseases.

Socio-economic deprivation and health outcomes (high incidence of respiratory and digestive diseases, and high level of mortality particularly due to infectious, respiratory or digestive diseases).

Pearson correlation between socio-economic deprivation index components and specific mortality and morbidity show significant associations. Only the significance level under 0.001 are considered, meaning that statistically significant correlations are between mortality due to infectious diseases and mortality due to tuberculosis (r=0.85, df= 64, p<0.001), morbidity due to respiratory diseases and economic status index (r=0.32, df= 64, p<0.001), morbidity due to respiratory diseases and housing endowment index (r=0.41, df= 64, p<0.001), morbidity due to digestive diseases and housing endowment index (r=0.27, df= 64, p<0.001).

There is no significant correlation between mortality due to infectious diseases and economic status index, too. There is a poor correlation between education level and mortality due to respiratory diseases. The reduced data availability could explain these inconsistency. Social and economic deprivation explained more of the variation in inequalities in health outcomes. Better level education, decent living conditions and higher economic status could improve population health outcomes (Figure 6).

Conclusions

The study aimed to analyse the relationship between population health outcomes and socioeconomic deprivation in Ialomița County, identifying territorial inequalities. Deprived areas overlap regions with high incidence of respiratory and digestive diseases and high level of mortality due to infectious, respiratory or digestive diseases.

There are significant differences between urban and rural areas regarding socio-economic deprivation. Preliminary results showed that economic status, living conditions and education level have an influence on population health outcomes, being often associated with good or poor health outcomes.

The study findings indicated that unemployment, poor housing conditions and low education level were associated with higher mortality and morbidity due to various diseases. The results demonstrated associations between health and socio-economic deprivation, mainly those related to low income or unemployment, poor access to facilities as flush toilets and sewerage, lack of formal education or illiteracy.
